Abstract. Colloidal undoped CdS and doped CdS:Mn nanoparticles were synthesized in the solution of polyvinyl alcohol polymer, and the process of nanoparticles growth was monitored by optical absorption measurements. The inclusion of Mn2+ impurity was checked by electron paramagnetic resonance measurements. It is shown that the core of CdS:Mn nanoparticle is undoped. The results obtained demonstrated that the rate of the band gap value decrease during nanoparticles growth is slower for the Mn-doped nanoparticles as compared to the undoped ones. This effect was ascribed to the inhibition of nanoparticles growth in the solution containing manganese salt. The model of the adsorptive doping of CdS NPs with manganese was proposed.

Keywords: colloidal synthesis, nanoparticles, doping, CdS:Mn.

1. Introduction

The insertion of just a few impurity atoms into a host semiconductor nanoparticle (NP) can drastically alter its phase, shape, and physical properties. The synthesis of doped nanomaterials with a specific dopant at a desired site in a host that leads to targeted physical properties requires fundamental understanding of the doping process. Colloidal doped NPs have drawn considerable attention in recent years because of their unique optical, electronic, and magnetoptical properties that stimulate potential applications in optoelectronic devices, biomedical labelling, etc. [1–4].

One particularly interesting and potentially beneficial approach is the synthesis of hybrid materials, consisting of inorganic doped NPs and organic polymers [5]. Such a combination may facilitate the application of unique properties of NPs by providing compatibility with existing techniques of polymers processing. Determination of the conditions and consistent patterns of the formation of crystal nuclei of adsorptionally/chemically alloyed NPs in aqueous polymeric solutions and studies of their physicochemical properties are a pressing problem of modern nanoelectronics. In these hybrids the role of high-molecular substances lies in controlling the size and the form of NPs, avoiding their aggregation and surface oxidation. Such nanostructures are used in the solar cells, biosensors, sources of light [6-9]. Understanding of how nanoparticles grow in various media is important inrationally designing synthetic routes to high quality composite colloids of desirable morphology and composition.

In the present study we used optical methods as one of the most available to study in the building of NPs and magnetic resonance methods to control the magnetic dopant incorporation. We first discuss the synthesis of polymer hybrid colloids containing either undoped or doped colloidal NPs in the solution of polyvinyl alcohol (PVA) and analyse how each step of synthesis influences

the band gap of NPs. We then demonstrate the presence of the embedded impurity in colloidal NPs by EPR measurements. Finally, we propose a scheme of the doping of NPs with the magnetic impurity for the system (PVA-H₂O-CdS:Mn nanoparticles).

2. Synthesis details and characterization techniques

Colloidal semiconducting NPs, both undoped CdS and CdS:Mn, were synthesized in the water solution of polyvinyl alcohol (PVA). The precursors for undoped CdS NPs (Cd²⁺ and S²⁻ ions) were injected into the growth solution sequentially via step-wise additions of equal amounts of CdCl₂ and Na₂S salts solutions. The presence of the capping molecules of polymer secured the restriction of NPs growth and formation of the stable colloid. The detailed sequence of the synthesis procedures is shown in Fig. 1.

To synthesize Mn-doped NPs the water solution of the salt MnCl₂ was added to the initial growth solution of PVA before adding other precursors. Afterwards the growth was conducted by the same sequence of precursors additions as above. The detailed quantitative characteristics of the growth solution composition at different stages of the synthesis are listed in Table. All source chemicals were chemically pure. The concentration of salts solutions in all cases was 0.1 mol/l. The bi-distilled water was used for solutions preparation. The synthesis conditions (pH values and precursors concentrations) were adjusted to meet the conditions of colloid formation and to avoid precipitation of MnS, Mn(OH)₂ and Cd(OH)₂. Concentration of polymer in the initial growing solution was 5 wt.%, concentration of Mn²⁺ was 5·10⁻³ M, concentration of Cd²⁺ ions varied in the range (1–30 mM). All synthesis steps were done at ambient conditions.

Absorption spectra were measured using MDR-24 grating monochromator at room temperature. The UV-lamp was used as the light sources.

For EPR measurements the thin self-standing films of semiconductor nanoparticles/PVA nanocomposites were used. They were formed by drying the colloidal solutions in Petri dishes in the chamber containing vapor-adsorbing substances at room temperature. EPR measurements were carried out using X-band (~9.5 GHz) spectrometer “Radiopan” at room temperature.

3. Results and discussion

To study the variation of the NPs size with the sequential addition of the precursors to the growth solution we measured the spectral dependences of the optical density of the colloidal solutions at every step of synthesis. As was shown in [10], the position of the optical absorption edge reflects the change of the average radius of NPs in the solution, thus these measurements can provide information about the NPs size during the growth.

Fig. 2 and 3 present the experimental data on the optical density of colloidal solutions of NPs CdS and CdS:Mn at different stages of synthesis (for the details see Table). The curves for the stage 1 are not shown in the Figs 2 and 3 because the starting growth solution is transparent in the whole spectral range studied.

Based on the above experimental data, the optical bandgap (E_g) of NPs in the solutions was estimated using the second derivative approach [11]. Fig. 4 shows the dependence of the calculated band gap of NPs on the concentration of precursors. Note that the precursor concentration value shown on the horizontal axis of the plot reflects the amount of precursors that have already took part in the chemical reaction, i.e., this concentration is equivalent to the content of CdS compound in the growth solution.

It is seen that with the increasing of precursors concentration the band gap of both undoped and doped NPs decreases in agreement with previous observations.

by other researchers [12, 13]. However, while at the initial stages of synthesis (the concentration of salts < 5·10^{-3} M) the band gap of doped and undoped NPs is almost the same, the further variation of the band gap is very different for the two types of NPs, and at the final stages of growth the band gap value of doped NPs is by almost 120 meV larger as compared to undoped NPs.

To analyze the discrepancies in the band gap behavior of undoped and doped NPs, one should consider two main factors that can influence the band gap value in the NPs under investigation. These factors are: i) the confinement-induced increase of the band gap in NPs [10], ii) the complex concentration-dependent variation of the band gap of CdS:Mn. The former factor is peculiar for both types of NPs while the latter one influences only the band gap of doped NPs. According to the literature data on the dependence $E_g$ vs. manganese content in bulk CdS:Mn [14] and nano-CdS:Mn [15] the band gap of CdS:Mn changes non-monotonously with concentration: in the range 0-4% of Mn the band gap value slightly decreases and in the range 4-40% the band gap increases almost by 300 meV.

Keeping in mind the above two factors we precede with the comparison of the band gap variation for undoped and doped NPs in course of colloid synthesis.

The equality of $E_g$ values of doped and undoped NPs at early stages of growth is indicative of the equivalence of the processes of nucleation in both cases. Thus one can conclude that nucleation of NPs in both growing procedures starts with the formation of undoped CdS seeds. This agrees with the findings of other authors [4, 16-19]. Upon further rising of the precursors concentration the distinctions in the values of the bandgap for the undoped and doped nanoparticles become more pronounced. To explain the difference in the $E_g$ values observed we will discuss two extreme cases when only one of the above factors is dominating.

If one assumes that size-dependent mechanism of band gap variation is dominating then one has to conclude that the presence of Mn in the solution strongly inhibits NPs growth. In this assumption the size of Mn-doped NPs has to be about 5.5 nm that is smaller than the average size of undoped NPs (~6.5 nm). Similar slowing of NPs growth due to the presence of ions of magnetic impurities was observed in [20].

In the framework of another extreme assumption one can ascribe difference in the band gap values of undoped and doped NPs solely to the influence of the Mn dopant. It means that we assume that CdS:Mn NPs have the same size as undoped CdS NPs and the band gap increase is totally composition-related.

According to [14, 15] the observed difference in $E_g$ that is equal to 120 meV points to Mn content of more than 20%. This doping level is rather high, so we have to check this assumption by some additional methods.

In order to get information about the presence of Mn$^{2+}$-ions in CdS particles the measurements of EPR are a helpful tool. Fig. 5 represents EPR spectrum of studied PVA/CdS:Mn nanoparticles nanocomposite. The spectrum demonstrates a multiple peak pattern that is characteristic of the Mn$^{2+}$ species. Observation of these six lines is usually assumed as a proof of Mn$^{2+}$ ions presence in the nanocomposite. More detailed study of the spectrum shows that the sextet observed is asymmetric and distance between the peaks is not constant. It means that at least two Mn positions must be taken into account at the analysis.

By analogy with the bulk materials, for the description of nanoobjects the same values of hyperfine interaction constant are used in literature [21, 22]. We used three components for the fitting of our spectra. The first fitting component with hyperfine interaction constant 70 Gauss is assigned to single Mn$^{2+}$-ions located in the bulk of NPs. The second component – with larger hyperfine-splitting of 95 Gauss – is assigned to Mn$^{2+}$-ions located in the near-surface positions in the NPs. Indeed, the Mn$^{2+}$-ions that are close to the surface must be less covalently bonded. This results in a higher density of the electron wavefunction on the manganese nucleus, and thus the hyperfine interaction must be stronger. The third fitting component is the broad line...
with peak to peak splitting of 500 Gauss. The latter line originates from the regions where Mn ions are situated very close to each other and Mn-Mn interactions are rather strong.

Thus, the observation of the two first components demonstrates that manganese is located both inside a NP and near its surface. Moreover, the presence of the third component shows that concentration of Mn is sufficiently high for manganese ions to interact. However, the overall view of the EPR spectrum evidences that the content of Mn$^{2+}$ cannot exceed a couple of percents. This latter fact leads to the conclusion that the dominating effect that controls the band gap of NPs is quantum confinement. Thus, the growth of NPs in the solution containing Mn ions is inhibited, the size of doped NPs is smaller compared to the undoped ones and doping leads only to minor variation of the band gap.

Fig. 4. Dependence $E_g$ of nanoparticles on the concentration of precursors of ions $\text{Cd}^{2+}$ and $\text{S}^{2-}$, which have reacted completely. Solid squares and blank triangles correspond to the calculated values of $E_g$ for CdS and CdS:Mn NPs, respectively. Lines are the guides for the eye.

4. Conclusion

In the present study, we have synthesized colloidal solutions of undoped CdS and doped NPs in PVA and formed solid films of NP/polymer composite. We have studied the absorption of both types of colloidal NPs at different stages of synthesis and have demonstrated that the absorption edge and, consequently, the band gap of NPs varies differently: at early stages of synthesis the band gap of both types of NPs is the same while it differs drastically when NPs grow larger. We have also measured EPR spectra of NP/polymer composite and demonstrated that the content of Mn cannot be very large, not exceeding couple of percents. Thus, we have concluded that introduction of Mn ions into the growth solution inhibits NPs growth. The model of the adsorptive doping of CdS NPs with manganese was proposed.
